ABSTRACT: Plants present different degrees of adaptation to aluminium (Al) concentrations in the soil, and the understanding of this characteristic can lead to a viable option for the utilization of acid soils. The objective of this experiment was to evaluate the effects of five Al concentrations (0, 50, 100, 200, and 400µmol L\(^{-1}\)) on the growth of ‘Rangpur’ lime (% Citrus limonia Osbeck) and ‘Volkamer’ lemon (% Citrus volkameriana Hort. ex Tan.), and tangerine rootstocks ‘Cleopatra’ (% Citrus reshni Hort. ex Tan) and ‘Sunke’ (% Citrus sunki Hort. ex Tan.), in hydroponic culture. The treatments were arranged in a randomized block design, with four replications. For all rootstocks, the relative growth rate in terms of plant total fresh matter increased under low and, decreased under large Al concentrations. Growth of the shoot, leaf area ratio and leaf weight ratio decreased for all rootstocks in the presence of Al. The ‘Rangpur’ lime had a decrease of the root system growth, starting from 23 µmol L\(^{-1}\) of Al. For the remaining rootstocks, this growth reached maximum values at 91 to 117µmol L\(^{-1}\) of Al, respectively. Considering all the evaluated characteristics of plant growth, the ‘Rangpur’ lime was the most susceptible to Al.

Key words: Citrus sp., relative growth rate, principal components, nutrient solution

INTRODUCTION

As citriculture expands worldwide, with a harvested area increasing from 6.2 million ha, in 1993, to 7.4 million ha in 2000 (FAO, 2000), and particularly in Brazil, where the harvested orange area evolved from 800 thousand ha, in 1993, to 1 million ha in 1999 (FNP Consultoria e Comércio, 2000), new cropping areas are under exploration. In these areas, the soil can present unfavorable conditions for the citrus crop, however, one of the major problems is aluminium (Al) toxicity, a limiting factor in many acid soils, which have an estimated extension between 40% and 70% of the soils available for agriculture (Rengel, 1992).

In the State of São Paulo, Brazil, approximately 70% of the soils where citiculture is practiced present restrictions to root growth due to soil Al. In other regions of Brazil, it is common to observe orchards established in soils originally covered by savanna (cerrado) vegetation, which have low fertility, high acidity and high Al concentration (Demattê & Vitti, 1992).

Anderson (1987) verified an increase in the productivity of ‘Valência’ orange trees grown on acid soil (pH = 5), increasing from 46 to 61 kg per tree and per year for plants grown on limed soil (pH = 7). In the State of Paraná, Brazil, Fidalski et al. (1999) verified a negative correlation between the fruit productivity of ‘Pêra’ orange
trees and the Al concentration in the soil, as well as with the total soil acidity.

Toxicity by Al cannot always be corrected economically by means of conventional liming practices (Foy, 1988). In several countries, one of the main reasons for this is that many areas that present soil acidity problems are distant from the agricultural lime production sites (Myers & Depauw, quoted by Ginter et al., 1998). Another difficulty is to correct acid strata that occur at greater depths in the soil, an acidity that in addition to that of the surface stratum, is increased due to the utilization of some nitrogen fertilizers, such as ammonium sulfate (Mason, 1980).

The variability in the adaptation to Al can be observed between plants of the same genus or between varieties of the same species (Nunes et al., 1995, Simon et al., 1994, Massot et al., 1999), and the use of genetic material that is tolerant or resistant to toxicity by Al becomes an important option for the occupation of acid soils.

With regard to rootstocks utilized in citriculture, Lin & Myhre (1991) concluded, based on the production of plant total fresh matter, that the citrus rootstocks evaluated by them could be classified, as to their tolerance to Al, in the following way: 'Cleopatra' tangerine > 'Rough' lemon > Citrus aurantium > 'Swingle' Citrumelo > 'Carrizo' citrange. Magalhães (1987) evaluated the tolerance of citrus rootstocks to Al added to the soil, verifying that Al significantly influenced the growth of the root system and of the aerial part, with the 'Rugoso da Florida' lemon as the most tolerant to Al, followed by the 'Cleopatra' tangerine and by the 'Rangpur' lime.

The generalized use of 'Rangpur' lime with the most diverse scions, soil types and climates does not adequately address the needs of all varieties, preventing the plant from expressing its complete productivity potential (Pompeu Jr., 1991). Therefore, the need for diversifying the rootstocks utilized in Brazilian citriculture becomes evident, decreasing the risk of an eventual outbreak of diseases or pests, and allowing the economic exploration of areas that present the most diverse edaphoclimatic conditions.

Toxicity by Al is morphologically characterized by the thickening and paralysis of root growth, due to cell wall hardening and cell division inhibition (Foy, 1978), and physiologically due to alterations in nutrient absorption and utilization, especially of P (Channel & Mielniczuk, 1983). Roots that have been damaged by aluminium are characteristically short, thick and brittle, with the absence of fine ramifications, and are very little efficient in absorbing water and nutrients (Foy, 1974). In addition to the root system, Al affects the growth of the shoot. The mechanisms that have been proposed to explain alterations caused by Al include: a) decreased cell division and elongation in the roots, resulting in limited exploration of the soil for nutrient and water absorption and translocation, b) interaction of Al with essential elements (Ca, Mg, P), resulting in decreased absorption and translocation of these elements, leading to deficiency symptoms, and, c) translocation of toxic amounts of Al to the aerial part of the plant (Foy, 1988).

There is much research carried out in relation to annual crops with the objective of evaluating the effects of aluminium on plant growth. However, for fruit tree species in general, and particularly for citrus, there are few published reports on the subject. Since growth-related characteristics constitute the criterion utilized to identify the degree of tolerance to aluminium for a species or variety, it is important to evaluate the effect of aluminium on citrus rootstock growth, extending the commercial exploration of soils to those that show high concentration of that element in the strata explored by the root system.

The objective of this research was to evaluate the effects of aluminium on the growth of the root systems and aerial parts of four citrus rootstocks.

**MATERIAL AND METHODS**

This research was carried out in a greenhouse located in Viçosa, MG, Brazil, during the period February to April, 1998.

Mature fruits were harvested from rootstock plants, seeds washed, selected, demucilaged, rinsed in running water, and left to dry in the shade for a week. After drying, a dry treatment was performed with the fungicide captan at a rate of 500 mg of active ingredient per each 100 g of seeds. Next, the seeds were stored for a month in a cold storage chamber at 5°C, and then sown in plastic boxes containing vermiculite as substrate for germination. They were irrigated, whenever necessary, with Hoagland solution containing 1/4 of its original concentration of salts. The seedlings, with a mean height of 7.7 cm, were selected according to size and transferred to 12 L-capacity Styrofoam boxes, containing Hoagland nutrient solution modified according to Simon et al. (1994), consisting of the following salts: 500 µmol L⁻¹ KNO₃; 500 µmol L⁻¹ Ca(NO₃)₂.4H₂O; 200 µmol L⁻¹ MgSO₄.7H₂O; 100 µmol L⁻¹ KH₂PO₄; 50 µmol L⁻¹ KCl; 46 µmol L⁻¹ H₃BO₃; 20 µmol L⁻¹ Fe-EDTA; 2 µmol L⁻¹ MnCl₂.4H₂O; 1 µmol L⁻¹ ZnSO₄.7H₂O; 0.3 µmol L⁻¹ CuSO₄.5H₂O and 0.5 µmol L⁻¹ NaMoO₄.2H₂O. Seven days later, the Al was added to the solution in the form of Al₃(PO₄)₂.18H₂O.

The solution was aerated by means of and air compressor. The pH in the solution was monitored daily and maintained at 4.0 by adding 0.1 mol L⁻¹ HCl or NaOH solutions, as necessary. Initially, the solutions were changed every two weeks; later on, during the last month, they were changed weekly. Each box received two seedlings of each rootstock, totaling eight seedlings.

The plants were grown for 70 days under natural photoperiod and room temperature conditions (21°C minimum, 35°C maximum and 28°C mean).

The factors under study were five concentrations of Al in the nutrient solution (0, 50, 100, 200, and 400 µmol L⁻¹) and four citrus rootstocks: 'Rangpur' lime (Citrus
Citrus rootstocks under aluminium stress

*limonia* Osbeck) and ‘Volkamer’ lemon (*Citrus volkameriana* Hort. ex Tan.), and ‘Cleopatra’ (*Citrus reshi* Hort. ex Tan.) and ‘Sunki’ (*Citrus sunki* Hort. ex Tan.) tangerines.

The experiment was carried out in a split-plot scheme, where plots corresponded to Al concentrations and sub-plots were rootstocks. The treatments were distributed in a randomized block design, with four replicates. Each experimental unit consisted of two plants.

The fresh matter mass of the entire plant was determined at the beginning and at the end of the experiment, and based on these values the relative growth rate (RGR) was estimated, according to Hunt (1990): 

$$RGR = \frac{\ln Y_2 - \ln Y_1}{t_2 - t_1}$$

where, 

- \( RGR \) = relative growth rate; 
- \( Y_1 \) = fresh matter mass at time \( t_1 \); 
- \( Y_2 \) = fresh matter mass at time \( t_2 \).

The leaf area was determined with a portable area-measuring device (DELTAT-T, model Mk2, Delta-T Devices Ltd., England). Later on, samples were placed in a forced-ventilation oven at 70°C to constant weight, and the dry matter masses for root and shoot were determined. The root/shoot ratio was estimated based on orthogonal contrasts (Table 1) of the relative growth rate; 

$$\text{Table 1 - Coefficients of orthogonal contrasts utilized to}$$

submitting to principal components analyses (Cruz & Regazzi, 1994; Johnson & Wichern, 1998; SAS Institute, 1999). The rootstock clustering was based on the Tocher method, applied to the principal component scores.

**RESULTS AND DISCUSSION**

In all rootstocks, the relative growth rate (RGR) initially increased in the presence of aluminium in the nutrient solution, reaching maximum values between 15 and 35 µmol L\(^{-1}\) of Al for the ‘Rangpur’ lime (CR) and the ‘Cleopatra’ (CL) tangerine, respectively. The RGR was smaller in the presence of higher concentrations. This initial increase, in percentage values, was higher for the tangerines. For the original values, the lemons presented higher RGR values in the absence of aluminium in the nutrient solution (Figure 1). In percentage values, the RGR for the ‘Sunki’ (SK) tangerine was more affected as compared to the CL tangerine (Tables 2 and 3). No difference was detected between the two lemons, the growth of which was more affected by aluminium as compared to the two tangerines.

The results obtained in this research are in agreement with those reported in other researches carried out with different species, in which aluminium caused a decrease in the relative growth rate (Oleksyn et al., 1996; Neogy et al., 1999). According to Lin & Myhre (1991), the total fresh matter of several citrus rootstocks submitted to low aluminium concentrations (<100 µmol L\(^{-1}\)) increased relative to the control, decreasing with the increase in Al concentration.

The possible mechanisms that caused the initial increase in RGR, at low Al concentrations, could be the same as for the net photosynthesis rate, i.e.: a) in acid solutions containing low Al concentrations, competition of Al\(^{3+}\) with H\(^+\) occurs for absorption sites on the cell surface (Kinraide & Parker, 1987), and b) Al\(^{3+}\) stimulates H\(^+\) extrusion, which is essential for root growth in acid pH (Yan et al., 1992), since, with the exception of the ‘Volkamer’ lemon (VL) tree, initial increases in net photosynthesis rate (Pereira et al., 2000) and RGR were verified, and these are indicative that the increase in RGR was due to the increase in the net photosynthesis rate.

For all rootstocks under evaluation the dry matter mass of the root system (DMMRS) increased in the presence of low aluminium concentrations, and the maximum values were obtained with the estimated doses of 36 (CR) to 117 (VL) µmol L\(^{-1}\) Al. The smallest percentage increases were verified for the ‘Rangpur’ lime. In the absence of Al, the highest absolute values were verified for the two lemons (Figure 1). For relative values, considering the mean for the five Al concentrations, the greatest inhibition of root dry matter accumulation was observed for the ‘Rangpur’ lime. When compared with the two tangerines, the lemons experienced greater inhibition, but this difference was due to the CR lemon (Tables 2 and 3).

Nogueira et al. (1989) did not verify any Al effect on dry matter production of the ‘Volkamer’ lemon tree root system at aluminium concentrations from 0 to 2,222 µmol L\(^{-1}\). However, at the concentration of 555 µmol L\(^{-1}\), they verified an increase, relative to the control, of 51% and 8% on ‘Sunki’ and ‘Rangpur’ lime, respectively, while a decrease occurred at the highest concentrations. Similarly to the results obtained in this experiment, the authors also verified a higher sensitivity of ‘Rangpur’ lime to Al.

Pinto (1999) verified that the dry matter in the root system of ‘Volkamer’ lemon seedlings grown at a concentration of 370 µmol L\(^{-1}\) Al presented increases up to 169%, as compared to seedlings grown in the absence of Al in nutrient solution. Therefore, the dry matter of the root system is such a characteristic that, in most situations, would not be the most suitable to evaluate the degree of aluminium tolerance.

The total length and area of the root system (TLRS and TARS) increased up to a certain Al concentration, reaching their maximum at an estimated value from 23 (CR) to 103 (VL) µmol L\(^{-1}\) Al (Figure 2). In relative values, the ‘Rangpur’ lime was the most affected by aluminium in relation to total length and area in the root system. With respect to total length, the ‘Sunki’ tangerine was more inhibited as compared to ‘Cleopatra’ (Tables 2 and 3). Clune & Copeland (1999) observed maximum growth of canola roots in the presence of 40 µmol L\(^{-1}\) Al in the nutrient solution, due to an increase in size and number of cells; at higher concentrations, root growth inhibition occurred. In addition, according to Santos et al. (1999), the root system length in ‘Rangpur’ lime seedlings exposed to 277 µmol L\(^{-1}\) Al, for 84 days, decreased 21% relative to the control. In ‘Swingle’ citrumelo, however, it decreased 49%.

With the exception of the ‘Rangpur’ lime, the values for the three evaluated characteristics (DMMRS, TLRS and TARS), up to a concentration of 400 µmol L\(^{-1}\) Al, were higher than those obtained in the absence of aluminium in the nutrient solution (Figures 1 and 2), which would apparently indicate beneficial effects of the aluminium on the root system functionality, responsible for water and nutrient absorption. However, this absorption occurs especially through absorbing root-hairs present in the lateral roots (Kowloski & Pallardi, 1997), the amount of which, in this experiment, increased only up to 50 µmol L\(^{-1}\) aluminium. For higher concentrations, root segments were thicker, a gradual decrease was verified in the amount of lateral roots, and consequently, of absorbing root-hairs.

Table 2 - Mean values of growth characteristics, relative to the control (=100%), of five aluminium rates, for ‘Rangpur’ lime (CR) and ‘Volkamer’ lemon (VL) and for ‘Sunki’ (SK) and ‘Cleopatra’ (CL) tangerines.

Lim. = Lemon and lime; Tan. = Tangerine. *, **: significant at 5 and 1%, respectively, by F test.
The leaf area and the dry matter mass of leaves (DMML) decreased in the presence of aluminium in the nutrient solution for all evaluated rootstocks (Figure 3). In relative values, the greatest decrease was observed for the ‘Rangpur’ lime (Tables 2 and 3), and no differences were detected between the tangerines. Because of the greater decrease in DMML verified for ‘Rangpur’ lime, the mean relative value of the lemons was significantly lower as compared to the tangerines.

Figure 1 - Relative growth rate of plant total fresh matter (RGR) and dry matter of the root system (DMMRS) for ‘Rangpur’ lime (CR) and ‘Volkamer’ lemons (VL) and for ‘Sunki’ (SK) and ‘Cleopatra’ (CL) tangerines, as a function of the aluminium (Al) concentration in the nutrient solution.

* Scientific Agricola, v.60, n.1, p.31-41, Jan./Mar. 2003
According to Nogueira et al. (1989), the leaf dry matter mass for ‘Volkamer’ lemon and ‘Rangpur’ limes and ‘Sunki’ tangerine decreased linearly with the increase of Al concentration in the nutrient solution, and for the highest concentration there were decreases of 63%, 58% and 41%, respectively, in relation to the control. Vasconcellos et al. (1989) verified linear decreases in leaf dry matter of ‘Rangpur’ lime and ‘Cleopatra’ tangerine seedlings, submitted to aluminium levels in the soil utilized as substrate. According to Santos et al. (1999), the leaf area and the dry matter mass of leaves of ‘Rangpur’ lime, decreased from 19% to 23% in the presence of aluminium. In addition to reducing the photosynthesis rate (Pereira et al., 2000), aluminium...
caused a decrease in leaf area, with lower production of photoassimilates utilized for plant growth. As a result, the rootstocks grew less, especially in the aerial part.

The root/shoot dry matter ratio (RSDMR) for all rootstocks reached a maximum value (1.3 mg mg⁻¹) at estimated concentrations from 235 to 260 µmol L⁻¹ aluminium (Figure 4). The greatest percentage increase was verified for the ‘Cleopatra’ tangerine, and no differences were detected between the two lemons. When the two tangerine are compared to the two lemons, a higher increase was verified for the tangerines, and this can be credited to ‘Cleopatra’ (Tables 2 and 3).

In Prunus cerasus seedlings, there was a 188% increase in RSDMR when grown in a solution containing

2,222 µmol L\(^{-1}\) Al, decreasing at higher Al concentrations (Borkowska, 1991). Similar effects were verified for sorghum plants growing in a nutrient solution containing 100 µmol L\(^{-1}\) Al (Hodson & Sangster, 1993). Pinto (1999) also verified that a 370 µmol L\(^{-1}\) Al concentration in the nutrient solution, can cause an increase in RSDMR for several citrus rootstocks. On the other hand, according to data presented by Santos et al. (1999), the presence of aluminium did not change this characteristic, both for the ‘Rangpur’ lime and the ‘Swingle’ citrumelo.

The increase in RSDMR verified in this experiment was due to the Al action, which made the leaf dry matter mass decrease (Figure 3) and caused an increase in root dry matter mass of three of the rootstocks under evaluation (Figure 1). This indicates that, under stress conditions, the plants allocated a greater amount of photoassimilates to the root system, in detriment to the aerial part. According to the quantitative model for the root/shoot ratio proposed by Thornley (1972), nutrient deficiencies, especially in N and P, increase the allocation of photoassimilates to the root system. This increase depends on the nutrient translocation from the aerial part to the root system (Marschner et al., 1996).

In this experiment a decrease in P content in the aerial part of all rootstocks was verified (Pereira, 2001), and this could have been one of the reasons for the increase in RSDMR. Effects similar to those of P deficiency on this ratio in soybean plants were verified by Freedon et al. (1989).

In all rootstocks under evaluation, both the leaf area ratio (LAR) and the leaf weight ratio (LWR) initially decreased up to a concentration from 245 (CR) to 292 (SK) µmol L\(^{-1}\) Al in the nutrient solution, and an increase in these characteristics occurred in the presence of higher Al concentrations (Figure 5). In relative values, the smallest decrease was verified for the ‘Sunki’ tangerine as compared to ‘Cleopatra’ (Tables 2 and 3). For the ‘Volkamer’ lemon there was a greater decrease in LWR as compared to ‘Rangpur’ lime.

The LAR is a morphological index of leaf area density, which allows a knowledge on the balance between the potentially photosynthesizing and the respiratory components of the plant (Hunt, 1990). The LWR measures the leafy character of plants based on dry matter, providing a knowledge on their potential in supporting the existing dry matter mass, as well as increasing it through photosynthesis (Beadle, 1993). Therefore, in this experiment, Al negatively affected the ability of all rootstocks to maintain and, or increase the existing dry matter, by rising the potential respiratory component of the plant.

Based on data presented by Pinto (1999), for ‘Rangpur’ lime seedlings exposed to 370 µmol L\(^{-1}\) Al, a 27% decrease in LAR was verified, while for ‘Cleopatra’ tangerine seedlings the decrease was 15%. On the other hand, based on data of Santos et al. (1999), no aluminium effect on LAR was verified for two evaluated

Figure 4 - Root/shoot dry matter ratio (RSDMR) for ‘Rangpur’ lime (CR) and ‘Volkamer’ lemon (VL) and for ‘Sunki’ (SK) and ‘Cleopatra’ (CL) tangerines, as a function of the aluminium (Al) concentration in the nutrient solution.

Scientia Agricola, v.60, n.1, p.31-41, Jan./Mar. 2003
citrus rootstocks. According to data presented by Pinto (1999), ‘Rangpur’ lime and ‘Cleopatra’ tangerine seedlings exposed to 370 \( \mu \text{mol L}^{-1} \) Al presented a decrease of 17.4 and 18.2% in LWR, respectively. As the concentration of Al in the nutrient solution increased, there was a decrease in leaf area and dry matter mass for all rootstocks (Figure 3). This caused a decrease in LAR and LWR, since the total dry matter mass was less
affected, due to the increase in root dry matter mass in three (CR, SK and CL) of the evaluated rootstocks (Figure 1).

The principal components analysis, applied to the correlation matrix of relative values of growth characteristics, allowed two principal components to be identified, which represent 94% of the total variance of the original characteristics (Table 4). The first component represents the relative growth of the plant. The second principal component represents a contrast between the relative growth of the aerial part against the relative growth of the root system (Table 3). Therefore, if a given rootstock presents higher scores relative to another, it is because it presents higher relative values of root growth.

According to the classification based on scores of the first two principal components, it can be verified that, considering all growth-related characteristics, the ‘Rangpur’ lime was the most sensitive rootstock to aluminium (Figure 6). On the other hand, the ‘Cleopatra’ tangerine tree presented the greatest tolerance to aluminium. These results coincide with those reported by Lin & Myhre (1991) and Pinto (1999), who consider the ‘Cleopatra’ tangerine as one of the most tolerant citrus rootstocks to aluminium. The differences in behavior of the evaluated rootstocks facing aluminium stress could be due to the differential expression of one or more mechanisms of exclusion or internal tolerance to aluminium, described by Taylor (1991; 1995) and Kochian (1995). The classification of the rootstocks ‘Rangpur’ lime and ‘Cleopatra’ relative to their tolerance to aluminium, based on growth characteristics, coincides with the classification based on the characteristics of gaseous exchanges and chlorophyll a (Pereira et al., 2000).

Table 4 - Eigenvectors in two principal components (PC1 and PC2) of values relative to the control, for dry matter mass in the root system (DMMRS); of the total area in the root system (TARS); of the total length of the root system (TLRS); of the leaf area (LA); of the dry matter mass in the leaves (DMML) and of the relative growth rate of the total fresh matter mass (RGR) of four citrus rootstocks submitted to aluminium stress.

<table>
<thead>
<tr>
<th>Characteristic</th>

</tr>
</tbody>
</table>

\( \lambda \) = Eigenvalue of the correlation matrix. CVA = cumulative variance.

Figure 6 - Clustering of ‘Rangpur’ lime (CR) and ‘Volkamer’ lemon (VL) and of ‘Sunki’ (SK) and ‘Cleopatra’ (CL) tangerines, based on scores of the first and second principal components.
