ACTIVITY OF CELLULASE FROM 
***THERMOACTINOMYCETES AND BACILLUS*** spp. 
ISOLATED FROM ***BRASSICA*** WASTE COMPOST

ABSTRACT: Plant wastes present a high cellulose content, which is an ideal organic material for composting. Five strains of thermophiles from processed *Brassica* waste were isolated, and the hydrolytic activity on various cellulosic biomass substrata and their temperature profiles were determined. 16S rRNA sequencing identified these strains as *Thermoactinomyces* and *Bacillus* spp. Maximal cellulase activity corresponded to 2.3 U mL⁻¹ of enzyme. The application of these strains on *Brassica rapa* residues demonstrates increased total nitrogen content). TA-3, a *Thermoactinomyces* sp. strain, performs best among all inoculants, increasing the nitrogen content from 0.74 to 0.91%, and decreasing the carbon content from 15.4 to 12.2%, showing its high efficiency and bioactivity during composting.

Key words: cellulose degrading, enzymes, vegetable wastes

INTRODUCTION

Agricultural waste generated in field and processing sites is generally discarded without being further used. If this waste is not properly handled, it may create a large environmental burden. Approximately 4.2 million metric tons of agricultural waste is produced annually in Taiwan (COA, 2006). Yang (1997) stated that fruit and vegetables account for almost 15% of total waste produced, comprising 570,000 metric tons of matter with high cellulose content. This waste can be handled in several ways, including direct combustion, landfill and composting. Among these methods, composting is considered the optimum approach for regulating soil fertility and minimizing the environmental impact.

Cellulose is the most common carbohydrate occurring in plants throughout the world. In fruit and vegetables, cellulose comprises almost 50% of carbohydrate, while hemi-cellulose comprises 15–34% (Das & Singh, 2004 and Reddy & Young, 2005). Most of these compounds are difficult to decompose rapidly in the natural environment (Knauf & Moniruzzaman, 2004 and Reddy & Young, 2005). Various microorganisms isolated from compost have been identified (McCaig et al., 2001; Song et al., 2001 and Das & Singh, 2004). Interest in these microorganisms has increased owing to potential commercial applications, namely biodegradation and production of bioactive compounds, including antibiotics and enzymes (Malherbe & Cloete, 2002; Kirk et al, 2002; Lynd et al., 2005). The composting process used for decom-
posing vegetable and fruit waste can be accelerated by adding cellulose-production thermophile. Organic matter in soil crucially influences soil systems and increases crop productivity. The application of compost in soil provides a key source of plant nutrients, and improves soil fertility, aeration, porosity, structure and water-holding capacity (Tuomela et al., 2000). With regard to natural systems, soil organic matter management is also essential for sustainable use of agricultural system, and for enhancing soil quality (Malherbe & Cloete, 2002).

**Brassica rapa** L. var. chinensis, also known as ‘Pak-Choi’, is one of the most popular vegetables among Chinese. Owing to the harvesting and sorting processes, over a thousand metric tons of waste are discarded annually in Taiwan. In this study, compost was produced from unwanted plant residue gathered from processing factories. Several strains of thermophilic microorganisms were then isolated from the compost and identified via 16S rRNA sequencing. The collected strains were tested for cellulase activity and temperature stability. The screened strains were then further applied to **Brassica rapa** residue to measure their ability to accelerate the composting process.

**MATERIAL AND METHODS**

A packed-bed reactor was adopted for making compost (Chang et al., 2004a and Chang et al., 2004b). Raw material such as unwanted outer leaf and stem of **Pak-Choi** were collected from a processing factory in Changhwa county (24°5' N, 120°32' E). 70% (w w−1) of water content from **Pak-Choi** was removed using drying chamber at temperature of 45°C for 8 h. The material was then mixed with rice husk (water content 10%) using a ratio of 5 to 1. Aeration was applied from the bottom of the reactor at a rate of 1.71 air kg−1 dry solids min−1. The entire composting process terminated after 90 d. Isolation of microorganism and determination of cellulase activity was undertaken during day 45. Ten to fifty g of compost sample was taken from the compost, and 50 mL sterile water was added. After shaking for 2 h under 200 rpm at 50°C, 1 mL of suspension was serially diluted and plated on a tryptic soy agar, modified M3 agar and potato dextrose agar (Huck et al., 1991).

Plates were incubated at 37°C and 50°C for 7 d. Isolates appeared on the plate were selected and plated on nutrient agar, bacterial selection agar, actinomycetes selection agar and fungal selection agar (Hagerman et al., 1985; Chang et al., 2004a and Chang et al., 2004b). Colonies appeared on selective agar were further used for cellulase activity testing. Cellulase activity was tested on Mandels-Reese agar (Bhat & Wood, 1988; Chang et al., 2004a). Briefly, isolate was plated on Mandels-Reese and cultivated at 50°C for 4 d, and 0.1% of Congo red was then sprayed on the colony. The diameter of the observed clear zone was then recorded.

Extraction of cellulolytic enzymes was referred to Zhang et al. (2006) with little modification. Cellulase-containing crude enzyme was prepared by centrifugation of culture broth at a rate of 12,000 x g and 4°C for 1 h. The supernatant was then filtered using 0.2 mm filter paper. Dinitrosalicylic acid (DNS) method (Miller, 1959) was applied to determine of cellulase activity. The DNS was prepared as described by Bhat & Wood (1988). Carboxymethylcellulose (CMC) was used as the substrate (Damasso et al., 2003). Glucose standard was used to plot the standard curve. Measurement of glucose released from CMC was expressed as Unit (U), in which, U = mg of glucose equivalents released min−1 mL−1 crude enzyme.

The genomic DNA of the samples was extracted by method described by Ng et al. (2006). The total 16S rRNA was amplified by primers BSF8 (52 -AGAGTTTGATCCTGCGTCAG-32 ) and BSF1507 (52 -TACCTTGTTACGACTT-32 ) (Ribosomal Database Project II). The PCR products were purified using a Gel Extraction kit, and subsequently ligated into pGEM®-T Vector Systems. The ligation product was transformed into an ECOS® competent cell screened using blue-white screening with IPTG and X-Gal. White colonies were selected and plated on an Luria-Bertani (LB) agar plate (bacto-tryptone 1%, yeast extract 0.5%, agar 1%) containing 50 μg mL−1 Ampicillin. 16S rRNA inserts were then amplified from the colonies by primers TAF (52 -CAAGGCGATTAAGTTGGGTA-32 ) and TAR (5-GGAATTTGAGCGATAACA-32 ) provided by the pGEM®-T Vector Systems. The amplified fragments were sequenced. Strains isolated were applied on **Brassica rapa** residue. Inoculation 1 × 10⁴ cell g−1 dry solid was performed, and the total duration of the composting process was 60 d. The composition of the plant residues was then analyzed. The total nitrogen level was tested by the Micro-Kjeldahl method (Singh & Pradhan, 1981). The total organic carbon (TOC) was estimated with Walkey and Black’s Rapid Titration method (1934). Levels of cellulose, hemicellulose and lignin were measured using the method described by Dutta (1981).1

**RESULTS AND DISCUSSION**

Five strains were screened, namely from Thermoactinomycetes and **Bacillus**, with 16S rRNA similarity in the range 95–99%, following BLAST
comparison in the NCBI database. The microorganisms were primarily mesophilic or thermophilic (Table 1). Actinomycetes comprise a diverse group of largely mycelial bacteria, many of which are ecologically important and have commercial potential for enzyme and antibiotic production (Edwards, 2007). Actinomycetes can degrade some cellulose, and solubilize lignin, and tolerate higher temperatures and pH than fungi. Actinomycetes thus are important agents of lignocellulose degradation during peak heating, among which *Thermoactinomycetes* is one of the genus that appear mainly during the cooling and maturation phase of composting (Tuomela et al., 2000). Previous assessment of soil diversity based on 16S rRNA has facilitated improved understanding of microbial diversity (Baker & Cowan, 2004), this universal and domain-specific region is molecule ubiquitous has numerous molecules, and also reflects functional constancy and is experimentally tractable (Woese, 2000).

Cellulose degradation is caused by various microorganisms, and represents a major carbon flow atmospheric CO₂ to fixed carbon. Fixed carbon has considerable potential for use in producing sustainable biobased products (Schloss et al., 2005). Results obtained by molecular systematic require further examination using other biochemical kits or tool because of the existence of some harmful microbes, such as *Thermoactinomycymes vulgaris*, which in addition to their amylolytic activity are also causative agents in lung disease (Allen & Hartman, 1972).

Generally, *Actinomycetes* and *Bacillus* strains isolated in this study released 2.0 mg glucose equivalents min⁻¹ mL⁻¹ enzyme (Table 2). These results were similar to those of Mayende et al. (2006), who found that *Bacillus* from compost exhibited cellulase activity. Numerous past studies have found the presence of thermophilic or thermo-tolerant *Bacillus* and *Actinomycetes* in compost (Blanc et al., 1999; Dees & Ghiorse, 2001; McCaig et al., 2001 and Mayende et al., 2006). Mayende et al. (2006) took compost samples from garden refuse, and identified screened microorganisms that were primarily thermophilic (60°C) or extremely thermophilic (70°C), with maximum cellulose activity of between 1.215–1.333 U. Five of the isolates identified in this work could utilize hydroxyethyl-cellulose and β-glucan. *Thermoactinomycetes* sp. (TA-1) was found to be able to utilize all the cellulose-containing materials (Table 3). A temperature of 50°C was recorded on day 45, demonstrating that most isolated strains were actively involved in the cellulose degradation process. Figure 1 illustrates the optimal temperatures of the isolates. All enzymes worked better at temperatures of 50°C, while those from TA-3 performed best at 60°C. The hydrolysis of CMC could be performed in 60–70 min. The dynamic of the enzymatic process reduced following 70 min for TA-2 and TB-1 (Figure 2).

Table 4 lists changes in nitrogen and carbon content in plant residue inoculated using different isolated strains. The Total Organic Carbon (TOC) of all five inoculants reduced, revealing mineralization of organic matter. Additionally, the Total Kjeldahl nitrogen (TKN) content of all inoculants increased. Notably, TA-3, a *Thermoactinomycetes* sp. performed best among

Figure 2 - Stability of cellulase activity in sample TA-1 to TA-3, TB-1 and TB-2. Values are expressed as mean of triplicates.

all inoculants, with nitrogen content increasing from 0.7% to 0.9%, and carbon content decreasing from 15.4% to 12.2% (Table 4). In cellulose content degradation, TA-3 performed best among all inoculants, which from 38.1% decreased to 15.2%. Overall performance of Thermoactinomyces on cellulose, hemicellulose and lignin were found better than those of thermophilic Bacillus. This result resembled the findings of Singh & Sharma (2002), who studied the impact of composting acceleration on bioinoculant efficiency. Non-inoculated wastes exhibited increased TKN and decreased TOC. Cellulose was considerably reduced following inoculation (Table 4). Similar results were also described by Rasal et al. (1988), who adopted cellulolytic fungi to decompose sugarcane trash.

This investigation has further confirmed the wide spread of Bacillus in natural composting systems. It also provides a feasible method of handling the large annual production of cellulose-containing substances. This study also further demonstrates that thermophiles...
isolated from a composting environment could produce thermophilic cellulases, which have potential industrial applications.
